Abstract

This paper provides two analytic approximation formulas for pricing ratchet caps in the LIBOR market model. The approximate values of a ratchet caplet are represented as sums of Black's (1976) regular caplet prices. So, these pricing formulas are extremely fast and easily implemented. The formulas can be easily extended to incorporate multiple factors. Illustrative numerical examples are provided and comparisons with results from Monte-Carlo implementation of the LIBOR market model are presented.

Keywords: LIBOR market model; Monte Carlo simulation; Ratchet Caps; Gauss-Hermite Integration.

The LIBOR market model or the BGM model, developed by Brace, Gatarek, and Musiela (1997), Jamshidian (1997), and Miltersen, Sandmann, and Sondermann (1997), has become an increasingly popular model for pricing interest rate derivatives over recent years. The pricing of interest rate derivatives in the LIBOR market model has usually resorted to Monte Carlo or finite difference methods as studied in Hull and White (2000), Hunter, Jackel and Joshi (2001), Pietersz, Pelsser and van Regenmortel (2002), Kurbanmuradov, Sabelfeld and Schoenmakers (2002) and others. While these numerical methods are flexible and yield accurate prices, they are very time consuming and expensive to use. The purpose of this paper is to develop accurate and computationally efficient approximation methods for pricing and hedging interest rate derivatives in the LIBOR market model. Although this paper focuses only on the ratchet caplet but the main idea in this paper will be easily applicable to other interest rate derivatives.

In this paper we suggest two approximation methods for valuing ratchet caps in the LIBOR market model. The results are surprisingly simple and the approximate values are represented as weighted sums of Black’s (1976) regular caplet prices. The weights are from Gauss-Hermite quadrature formula which can be easily calculated from standard numerical packages. So, our approximation methods are extremely fast and easily implemented.

The outline of this paper is as follows. Section I introduces the ratchet caplet. The developments of the first and second approximation methods are contained in Sections II and IV, respectively. Multi-factor extensions of two approximation methods are described in Sections III and V, respectively. Comparisons with results from Monte Carlo simulation are presented in Section VI. We conclude the paper in Section VII.
I. Ratchet Cap

One of the most interesting nonstandard caps is a ratchet cap. This is like a regular cap except that the cap rate equals the LIBOR rate at the previous reset date plus a spread. Define \( t_0 = 0 \) and consider a ratchet cap with reset dates \( t_1, t_2, \ldots, t_n \) and a final payment date \( t_{n+1} \). Suppose that the principal is \( L \) and the spread is \( s \). Define \( R_k \) as the interest rate for the period between time \( t_k \) and \( t_{k+1} \) observed at time \( t_k \) expressed with a compounding period of \( \delta_k = t_{k+1} - t_k \). The ratchet cap leads to a payoff at time \( t_{k+1} \) \((k = 1, 2, \ldots, n)\) of
\[
L \delta_k \max[R_k - (R_{k-1} + s), 0]
\]

By considering a world that is forward risk neutral with respect to a zero-coupon bond maturing at time \( t_{k+1} \), the equivalent martingale measure result of Harrison and Kreps (1979) and Harrison and Pliska (1981) says that the price of a ratchet caplet that provides a payoff at time \( t_{k+1} \) is
\[
L \delta_k P(t, t_{k+1}) E]\left[ \max[R_k - (R_{k-1} + s), 0] \bigg| R_{k-1} \right]\]
where \( P(t, t_{k+1}) \) is the price at time \( t \) of a zero-coupon bond with principal $1$ maturing at time \( t_{k+1} \) and \( E \) denotes the expected value in a forward risk neutral world with respect to \( P(t, t_{k+1}) \). By the law of iterated expectation, we have
\[
L \delta_k P(t, t_{k+1}) E]\left[ \max[R_k - (R_{k-1} + s), 0] \bigg| R_{k-1} \right] = \sum_{j=0}^{k-1} \delta_j \]
(1)

We note the fact that if we know \( R_{k-1} \) then the ratchet caplet is exactly a regular caplet with a cap rate of \( (R_{k-1} + s) \). Thus, if the conditional distribution of the rate \( R_k \), given \( R_{k-1} \), is assumed to be lognormal, then the conditional expectation in equation (1) can be evaluated using Black's (1976) model. This paper gives two analytic approximation formulas for the equation (1) by differently approximating the probability density function of \( R_{k-1} \) in a forward risk neutral world with respect to \( P(t, t_{k+1}) \).
II. First Approximation Method

Define $F_k(t)$ as the forward interest rate as seen at time $t$ for the period between $t_k$ and $t_{k+1}$ expressed with a compounding period of $\delta_k = t_{k+1} - t_k$ and $\zeta_k(t)$ as the volatility of $F_k(t)$ at time $t$. The processes followed by $F_k(t)$ and $F_{k-1}(t)$ in the forward risk neutral world with respect to $P(t,F_{k+1})$ are

\[
\frac{dF_k(t)}{F_k(t)} = \zeta_k(t)dz
\]

(2)

\[
\frac{dF_{k-1}(t)}{F_{k-1}(t)} = \frac{-\delta_k F_k(t) \zeta_k(t) \zeta_{k-1}(t)}{1 + \delta_k F_k(t)} dt + \zeta_{k-1}(t)dz
\]

(3)

where $dz$ is a Wiener process.

It is usual to assume that $\zeta_k(t) = \Lambda_{k-m(t)}$ where $m(t) = \min\{k : t \leq t_k\}$ is the index for the next reset date at time $t$. This means that $\zeta_k(t)$ is a step function only of the number of whole accrual periods between the next reset date and time $t_k$. The $\Lambda_i$ can be obtained iteratively by

\[
\sigma_i^2 t_k = \sum_{k=i}^{k=m(t)} \Lambda_i
\]

(4)

where $\sigma_i$ is the Black (1976) volatility for the regular caplet that corresponds to the period between times $t_k$ and $t_{k+1}$. Expressed in terms of the $\Lambda_i$'s equations (2) and (3) are, respectively,

\[
\frac{dF_k(t)}{F_k(t)} = \Lambda_{k-m(t)}dz
\]

\[
\frac{dF_{k-1}(t)}{F_{k-1}(t)} = \frac{-\delta_k F_k(t) \Lambda_{k-m(t)} \Lambda_{k-1-m(t)}}{1 + \delta_k F_k(t)} dt + \Lambda_{k-1-m(t)}dz
\]

or

\[
d \ln F_k(t) = -\frac{1}{2} \Lambda_{k-m(t)}^2 dt + \Lambda_{k-m(t)}dz
\]

(5)

\[
d \ln F_{k-1}(t) = \left( \frac{-\delta_k F_k(t) \Lambda_{k-m(t)} \Lambda_{k-1-m(t)}}{1 + \delta_k F_k(t)} - \frac{1}{2} \Lambda_{k-1-m(t)}^2 \right) dt + \Lambda_{k-1-m(t)}dz
\]

(6)

If we assume in the drift of $\ln F_{k-1}(t)$ in equation (6) that $F_k(t) = F_{k}(t_0)$ for $t_0 < t < t_{k-1}$, then the
drift remains constant within each accrual period and we have

\[
\ln F_k(t_k) = \ln F_k(t_0) + \sum_{j=0}^{k-1} \left[ -\frac{1}{2} \Lambda_{k-j-1}^2 \delta_j + \Lambda_{k-j-1} \varepsilon_j \sqrt{\delta_j} \right]
\]

(7)

\[
\ln F_{k-1}(t_{k-1}) = \ln F_{k-1}(t_0) + \sum_{j=0}^{k-2} \left[ -\frac{\delta_k F_k(t_0) \Lambda_{k-j-1} \Lambda_{k-j-2}}{1 + \delta_k F_k(t_0)} - \frac{1}{2} \Lambda_{k-j-2}^2 \delta_j + \Lambda_{k-j-2} \varepsilon_j \sqrt{\delta_j} \right]
\]

(8)

where \( \varepsilon_j \) (0 ≤ j ≤ k - 1) are random samples from a standard normal distribution.

Let \( X = \ln F_k(t_k) \) and \( Y = \ln F_{k-1}(t_{k-1}) \). Then a two dimensional random variable \((X, Y)\) has a bivariate normal distribution with means \( \mu_X \) and \( \mu_Y \), variances \( \sigma_X^2 \) and \( \sigma_Y^2 \), and correlation coefficient \( \rho_{XY} \) where

\[
\mu_X = \ln F_k(t_0) + \sum_{j=0}^{k-1} \left[ -\frac{1}{2} \Lambda_{k-j-1}^2 \delta_j \right]
\]

\[
\mu_Y = \ln F_{k-1}(t_0) + \sum_{j=0}^{k-2} \left[ -\frac{\delta_k F_k(t_0) \Lambda_{k-j-1} \Lambda_{k-j-2}}{1 + \delta_k F_k(t_0)} - \frac{1}{2} \Lambda_{k-j-2}^2 \delta_j \right]
\]

\[
\sigma_X^2 = \sum_{j=0}^{k-1} \Lambda_{k-j-1}^2 \delta_j
\]

\[
\sigma_Y^2 = \sum_{j=0}^{k-2} \Lambda_{k-j-2}^2 \delta_j
\]

\[
\rho_{XY} = \frac{1}{\sigma_X \sigma_Y} \sum_{j=0}^{k-1} \Lambda_{k-j-1} \Lambda_{k-j-2} \delta_j
\]

Using equation (4) and simplifying yields

\[
\sigma_X^2 = \sigma_X^2 t_k
\]

\[
\sigma_Y^2 = \sigma_Y^2 t_{k-1}
\]

\[
\mu_X = \ln F_k(t_0) - \frac{1}{2} \sigma_X^2
\]

\[
\mu_Y = \ln F_{k-1}(t_0) - \frac{\delta_k F_k(t_0) \rho_{XY} \sigma_X \sigma_Y}{1 + \delta_k F_k(t_0)} - \frac{1}{2} \sigma_Y^2
\]

Therefore, the expectation in equation (1) is
\[
E\left[\max\left[F_k(t_k) - F_{k-1}(t_{k-1}) - s, 0\right] | F_{k-1}(t_{k-1})\right] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \max(e^x - e^y - s, 0) f(x | y) dx \cdot f_Y(y) dy
\]

where the conditional probability density function \( f(x | y) \) of \( X \) given \( Y = y \) is normal with mean \( \mu_X + \rho_{XY} \frac{\sigma_X}{\sigma_Y} (y - \mu_Y) \) and variance \( \sigma_Y^2 (1 - \rho_{XY}^2) \) and the marginal probability density function \( f_Y(y) \) is normal with mean \( \mu_Y \) and variance \( \sigma_Y^2 \). The inner integral in equation (9) can be explicitly evaluated as

\[
\int_{-\infty}^{\infty} \max(e^x - e^y - s, 0) f(x | y) dx = E(e^X | y) N(d_1) - KN(d_2)
\]

where \( N(*) \) is the standard normal distribution function and

\[
d_1 = \frac{\ln[E(e^X | y)/K] + \sigma_Y^2 (1 - \rho_{XY}^2) / 2}{\sigma_X \sqrt{1 - \rho_{XY}^2}}
\]

\[
d_2 = \frac{\ln[E(e^X | y)/K] - \sigma_Y^2 (1 - \rho_{XY}^2) / 2}{\sigma_X \sqrt{1 - \rho_{XY}^2}} = d_1 - \sigma_X \sqrt{1 - \rho_{XY}^2}
\]

\[
E(e^X | y) = \exp \left[ \mu_X + \rho_{XY} \frac{\sigma_X}{\sigma_Y} (y - \mu_Y) + \frac{\sigma_Y^2}{2} (1 - \rho_{XY}^2) \right]
\]

\[
= F_k(t_0) \exp \left[ \rho_{XY} \frac{\sigma_X}{\sigma_Y} (y - \mu_Y) - \frac{1}{2} \sigma_X^2 \rho_{XY}^2 \right]
\]

\[K = e^y + s\]

so that

\[
E[E[\max[F_k(t_k) - F_{k-1}(t_{k-1}) - s, 0] | F_{k-1}(t_{k-1})]] = \int_{-\infty}^{\infty} [E(e^X | y) N(d_1) - KN(d_2)] f_Y(y) dy
\]

Note that \( E(e^X | y) \) is the conditional expectation of \( F_k(t_k) \) given \( F_{k-1}(t_{k-1}) \). If we change the variable of integration by writing

\[z = \frac{1}{\sqrt{2}} \frac{y - \mu_Y}{\sigma_Y}\]

then
\[ E[\max[F_k(t_k) - F_{k-1}(t_{k-1}) - s,0] \mid F_{k-1}(t_{k-1})] = \int_{-\infty}^{\infty} \frac{1}{\sqrt{\pi}} \left[ E(e^x \mid z)N(d_1) - KN(d_2) \right] e^{-z^2}dz \]  

where

\[ d_1 = \frac{\ln[E(e^x \mid z)/K] + \frac{1}{2} \sigma_x^2 (1 - \rho_{XY}^2) / 2}{\sigma_x \sqrt{1 - \rho_{XY}^2}} \]

\[ d_2 = d_1 - \sigma_x \sqrt{1 - \rho_{XY}^2} \]

\[ E(e^x \mid z) = F_k(t_0) \exp \left[ \sqrt{2} \rho_{XY} \sigma_x z - \frac{1}{2} \sigma_x^2 \rho_{XY}^2 \right] \]

\[ K = \exp(\mu_Y + \sqrt{2} \sigma_Y z) + s \]

The integral in equation (10) can be computed using various standard numerical integration techniques. The one best suited to evaluating the integral in equation (10) is Gauss-Hermite quadrature. By using \( N \)-point Gauss-Hermite quadrature formula, the approximated value, \( \hat{c}_k \), of a ratchet caplet that provides a payoff at time \( t_{k+1} \) is

\[ \hat{c}_k = L \delta_k P(t,t_{k+1}) \int_{-\infty}^{\infty} g(z)e^{-z^2}dz \approx L \delta_k P(t,t_{k+1}) \sum_{i=1}^{N} w_i g(z_i) \]  

(11)

where

\[ g(z) = \frac{1}{\sqrt{\pi}} \left[ E(e^x \mid z)N(d_1) - KN(d_2) \right] \]

and \( d_1, d_2, E(e^x \mid z) \) and \( K \) are as defined in equation (10). The weights \( w_i \) \((1 \leq i \leq N)\) and abscissas \( z_i \) \((1 \leq i \leq N)\) of the Gauss-Hermite quadrature formula can be calculated using GAUHER function in the Numerical Recipes program given by Press et al (1992). Note that the calculation of one ratchet caplet prices using \( N \)-point Gauss-Hermite quadrature formula with equation (11) requires \( N \) evaluations of Black's (1976) formula.
III. First Approximation Method with Several Factors

The first approximation method in the previous section can be easily extended to incorporate several independent factors. Suppose that there are \( p \) factors and \( \xi_{k,q}(t) \) is the component of the volatility of \( F_k(t) \) attributable to the \( q \)th factor. The processes followed by \( F_k(t) \) and \( F_{k-1}(t) \) in the forward risk neutral world with respect to \( P(t,t_{k+1}) \) are

\[
\frac{dF_k(t)}{F_k(t)} = \sum_{q=1}^{p} \xi_{k,q}(t)dz_q \tag{12}
\]

\[
\frac{dF_{k-1}(t)}{F_{k-1}(t)} = \frac{-\delta_{k}F_k(t)\sum_{q=1}^{p} \xi_{k,q}(t)\xi_{k-1,q}(t)}{1 + \delta_{k}F_k(t)}\ dt + \sum_{q=1}^{p} \xi_{k-1,q}(t)dz_q \tag{13}
\]

where \( dz_q \) (\( 1 \leq q \leq p \)) are independent Wiener processes.

Define \( \lambda_{i,q} \) as the \( q \)th component of the volatility when there are \( i \) accrual periods between the next reset date and time \( t_k \). The \( \lambda_{i,q} \)'s and \( \lambda_{i} \)'s are related with

\[
\lambda_i^2 = \sum_{q=1}^{p} \lambda_{i,q}^2 \tag{14}
\]

We approximate the drift in equation (13) by setting \( F_k(t) = F_k(t_0) \) for \( t_0 < t < t_{k-1} \). Then the drift remains constant within each accrual period and we have

\[
\ln F_k(t_k) = \ln F_k(t_0) + \sum_{j=0}^{k-1} \left[ -\frac{1}{2} \sum_{q=1}^{p} \lambda_{k-j-1,q}^2 \delta_j + \sum_{q=1}^{p} \lambda_{k-j-1,q} \xi_{j,q} \sqrt{\delta_j} \right] \tag{15}
\]

\[
\ln F_{k-1}(t_{k-1}) = \ln F_{k-1}(t_0) + \sum_{j=0}^{k-2} \left[ -\delta_{k}F_k(t_0) \sum_{q=1}^{p} \lambda_{k-j-1,q}^2 \lambda_{k-j-2,q} \right. \left. \frac{1}{1 + \delta_{k}F_k(t_0)} \delta_j + \sum_{q=1}^{p} \lambda_{k-j-2,q} \xi_{j,q} \sqrt{\delta_j} \right] \tag{16}
\]

where \( \xi_{j,q} \) (\( 0 \leq j \leq k-1, \ 1 \leq q \leq p \)) are random samples from a standard normal distribution.

Let \( X = \ln F_k(t_k) \) and \( Y = \ln F_{k-1}(t_{k-1}) \). Then a two dimensional random variable \((X,Y)\) has a
bivariate normal distribution with means $\mu_X$ and $\mu_Y$, variances $\sigma_X^2$ and $\sigma_Y^2$, and correlation coefficient $\rho_{XY}$ where

$$\mu_X = \ln F_k(t_0) + \sum_{j=0}^{k-1} \left[ -\frac{1}{2} \sum_{q=1}^{p} \lambda_{k-j-1,q} \delta_j \right]$$

$$\mu_Y = \ln F_{k-1}(t_0) + \sum_{j=0}^{k-2} \left[ -\delta_j F_k(t_0) \sum_{q=1}^{p} \lambda_{k-j-1,q} \lambda_{k-j-2,q} \frac{1}{1 + \delta_k F_k(t_0)} - \frac{1}{2} \sum_{q=1}^{p} \lambda_{k-j-2,q}^2 \delta_j \right]$$

$$\sigma_X^2 = \sum_{j=0}^{k-1} \sum_{q=1}^{p} \lambda_{k-j-1,q}^2 \delta_j = \sum_{j=0}^{k-1} [\lambda_{k-j-1}^2 \delta_j] = \sigma_X^2 t_k$$

$$\sigma_Y^2 = \sum_{j=0}^{k-2} \sum_{q=1}^{p} \lambda_{k-j-2,q}^2 \delta_j = \sum_{j=0}^{k-2} [\lambda_{k-j-2}^2 \delta_j] = \sigma_Y^2 t_{k-1}$$

$$\rho_{XY} = \frac{1}{\sigma_X \sigma_Y} \sum_{j=0}^{k-2} \sum_{q=1}^{p} \lambda_{k-j-1,q} \lambda_{k-j-2,q} \delta_j$$

The means $\mu_X$ and $\mu_Y$ are simplified as

$$\mu_X = \ln F_k(t_0) - \frac{1}{2} \sigma_X^2$$

$$\mu_Y = \ln F_{k-1}(t_0) - \delta_k F_k(t_0) \rho_{XY} \sigma_X \sigma_Y - \frac{1}{2} \sigma_Y^2$$

Note that $\sigma_X^2$, $\sigma_Y^2$, and $\mu_X$ are independent of the number of factors whereas $\rho_{XY}$ and $\mu_Y$ depend on the number of factors. The remaining analysis is same as that in the previous section. Therefore, the approximated value of a ratchet caplet with several factors can be calculated using equation (11) with the adjustments only of $\rho_{XY}$ and $\mu_Y$. 
IV. Second Approximation Method

For a more accurate approximation, we reconsider the drift of \( \ln F^*_k(t) \) in equation (6). If we assume in the drift of \( \ln F^*_k(t) \) in equation (6) that \( F^*_k(t) = F^*_k(t_0) \) for \( t_0 < t < t_1 \) and \( F^*_k(t) = F^*_k(t_1) \) for \( t_1 < t < t_{k-1} \), then equation (8) becomes

\[
\ln F^*_k(t_{k-1}) = \ln F^*_k(t_0) + \left( -\delta_0 + \frac{1}{2} \Lambda^2 \delta_0 \right) \sqrt{\delta_0} + \Lambda \varepsilon_0 \sqrt{\delta_0}
\]

\[
+ \sum_{j=1}^{k-1} \left[ \left( -\delta_0 + \frac{1}{2} \Lambda^2 \delta_0 \right) \sqrt{\delta_0} + \Lambda \varepsilon_0 \sqrt{\delta_0} \right]
\]

where

\[
\ln F^*_k(t_1) = \ln F^*_k(t_0) + \left[ -\frac{1}{2} \Lambda^2 \delta_0 + \Lambda \varepsilon_0 \sqrt{\delta_0} \right]
\]

and \( \varepsilon_j \) (\( 0 \leq j \leq k-1 \)) are random samples from a standard normal distribution.

Let \( X = \ln F^*_k(t_k) \), \( Y = \ln F^*_k(t_{k-1}) \) and \( A = \ln F^*_k(t_1) \). We note that the conditional distribution of \( Y \) given \( A \) is normal. Thus a two dimensional random variable \( (X, Y) \) given \( A = a \) has a bivariate normal distribution with means \( \mu_X \) and \( \mu_Y \), variances \( \sigma_X^2 \) and \( \sigma_Y^2 \), and correlation coefficient \( \rho_{XY} \)

where

\[
\mu_X = a + \sum_{j=1}^{k-1} \left[ -\frac{1}{2} \Lambda^2 \delta_0 \right]
\]

\[
\mu_Y = b + \sum_{j=1}^{k-1} \left[ -\frac{1}{2} \Lambda^2 \delta_0 \left( \frac{1}{1 + \delta_k e^{a}} \right) \right]
\]

\[
\sigma_X^2 = \sum_{j=1}^{k-1} \left[ \Lambda^2 \delta_0 \right]
\]

\[
\sigma_Y^2 = \sum_{j=1}^{k-1} \left[ \Lambda^2 \delta_0 \right]
\]

\[
\rho_{XY} = \frac{1}{\sigma_X \sigma_Y} \sum_{j=1}^{k-1} \Lambda^2 \delta_0 \delta_j
\]
\[ b = \ln F_{t_{k+1}}(t_0) + \left( -\delta_{i} F_{k}(t_0) \Lambda_{k-1} \Lambda_{k-2} - \frac{1}{2} \Lambda_{k-2}^2 \right) \delta_0 + \Lambda_{k-2} \left( a - \ln F_{k}(t_0) + \frac{1}{2} \Lambda_{k-1} \delta_0 \right) \]

The variable \( b \) is the value of \( \ln F_{t_{k+1}}(t_1) \) given \( A = a \). Using equation (4) and simplifying yields

\[
\sigma_X^2 = \sigma_Y^2 t_{k+1} - \Lambda_{k-1}^2 \delta_0
\]

\[
\sigma_Y^2 = \sigma_X^2 t_{k+1} - \Lambda_{k-2}^2 \delta_0
\]

\[
\mu_X = a - \frac{1}{2} \sigma_X^2
\]

\[
\mu_Y = b - \frac{\delta_{i} e^y \rho_{XY} \sigma_X \sigma_Y}{1 + \delta_{i} e^y} - \frac{1}{2} \sigma_Y^2
\]

Therefore, the expectation in equation (1) is

\[
E \left[ E \left[ \max \left[ F_{k}(t_1) - F_{k-1}(t_{k+1}) - s \right] \mid F_{k-1}(t_{k+1}), F_{k}(t_1) \right] \right]
\]

\[
= \int \int \left[ \int \max(e^x - e^y - s, 0) f(x \mid y, a) dx \right] f(y \mid a) f_A(a) dy da
\]

(17)

where the first conditional probability density function \( f(x \mid y, a) \) of \( X \) given \( Y = y \) and \( A = a \) is normal with mean \( \mu_X + \rho_{XY} \frac{\sigma_X}{\sigma_Y} (y - \mu_Y) \) and variance \( \sigma_X^2 (1 - \rho_{XY}^2) \), the second conditional probability density function \( f(y \mid a) \) is normal with mean \( \mu_Y \) and variance \( \sigma_Y^2 \), and the marginal density function \( f_A(a) \) is normal with mean \( \mu_A = \ln F_{k}(t_0) - \frac{1}{2} \sigma_A^2 \) and variance \( \sigma_A^2 = \Lambda_{k-1} \delta_0 \).

The inner integral in equation (17) can be explicitly evaluated as

\[
\int_{-\infty}^{\infty} \max(e^x - e^y - s, 0) f(x \mid y, a) dx = E(e^X \mid y, a) N(d_1) - KN(d_2)
\]

where \( N(*) \) is the standard normal distribution function and

\[
d_1 = \frac{\ln E(e^X \mid y, a) / K + \sigma_X^2 (1 - \rho_{XY}^2) / 2}{\sigma_X \sqrt{1 - \rho_{XY}^2}}
\]

\[
d_2 = d_1 - \sigma_X \sqrt{1 - \rho_{XY}^2}
\]

\[
E(e^X \mid y, a) = \exp \left[ \mu_X + \rho_{XY} \frac{\sigma_X}{\sigma_Y} (y - \mu_Y) + \frac{\sigma_X^2}{2} (1 - \rho_{XY}^2) \right]
\]
\[ K = e^y + s \]

so that
\[
E \left[ \max \left\{ F_k(t_k) - F_{k-1}(t_{k-1}) - s, 0 \right\} \mid F_{k-1}(t_{k-1}), F_k(t_1) \right] \\
= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[ E(e^y \mid y, a)N(d_1) - K N(d_2) \right] f(y \mid a)f_A(a) \, dy \, da
\]

If we change the variables of integration by writing
\[ z = \frac{y - \mu_y}{\sigma_y} \quad \text{and} \quad h = \frac{a - \mu_A}{\sigma_A} \]

then
\[
E \left[ \max \left\{ F_k(t_k) - F_{k-1}(t_{k-1}) - s, 0 \right\} \mid F_{k-1}(t_{k-1}), F_k(t_1) \right] \\
= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[ E(e^z \mid z, h)N(d_1) - K N(d_2) \right] e^{-z^2} e^{-h^2} \, dz \, dh
\]

where
\[
d_1 = \ln \left[ E(e^z \mid z, h)K + \sigma_Y^2 (1 - \rho_{XY}^2) / 2 \right] / \sigma_Y \sqrt{1 - \rho_{XY}^2} / 2 \\
d_2 = d_1 - \sigma_Y \sqrt{1 - \rho_{XY}^2} \\
E(e^z \mid z, h) = \exp(\mu_A + \sqrt{2} \sigma_A h) \exp \left[ \sqrt{2} \rho_{XY} \sigma_Y z - \frac{1}{2} \sigma_Y^2 \rho_{XY}^2 \right]
\]

The one best suited to evaluating the integral in equation (18) is Gauss-Hermite quadrature. By using \( N \) point Gauss-Hermite quadrature formula, the approximated value, \( \hat{c}_k \), of a ratchet caplet that provides a payoff at time \( t_{k+1} \) is
\[
\hat{c}_k = L \delta_k P(t, t_{k+1}) \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(z, h)e^{-z^2} e^{-h^2} \, dz \, dh \approx L \delta_k P(t, t_{k+1}) \sum_{i=1}^{N} \sum_{j=1}^{N} w_i w_j g(z_i, h_j)
\]

where
\[ g(z, h) = \frac{1}{\pi} \left[ E(e^X | z, h) N(d_1) - K N(d_2) \right] \]

and \( d_1, d_2, E(e^X | z, h) \) and \( K \) are as defined in equation (18). The weights \( w_i \ (1 \leq i \leq N) \) and abscissas \( z_i, h_i \ (1 \leq i \leq N) \) of the Gauss-Hermite quadrature formula can be calculated using GAUHER function in the Numerical Recipes program. Note that the calculation of one ratchet caplet prices using \( N \)-point Gauss-Hermite quadrature formula with equation (19) requires \( N^2 \) evaluations of Black’s (1976) formula.

\[ \text{V. Second Approximation Method with Several Factors} \]

The second approximation method in the previous section can also be easily extended to incorporate several independent factors. If we approximate the drift in equation (13) by setting \( F_k(t) = F_k(t_0) \) for \( t_0 < t < t_1 \) and \( F_k(t) = F_k(t_1) \) for \( t_1 < t < t_{k-1} \), then equation (16) becomes

\[ \ln F_{k-1}(t_{k-1}) = \ln F_{k-1}(t_0) + \left( -\delta_k F_k(t_0) \sum_{q=1}^{p} \lambda_{k-1,q} \lambda_{k-2,q} \lambda_{k-2,q} \left( 1 + \delta_k F_k(t_0) \right) - \frac{1}{2} \sum_{q=1}^{p} \lambda_{k-2,q}^2 \delta_0 \right) \delta_0 + \sum_{q=1}^{p} \lambda_{k-2,q} \epsilon_{0,q} \sqrt{\delta_0} \]

\[ + \sum_{j=1}^{k-2} \left( -\delta_k F_k(t_1) \sum_{q=1}^{p} \lambda_{k-1,q} \lambda_{k-j,q} \lambda_{k-j-2,q} \left( 1 + \delta_k F_k(t_1) \right) - \frac{1}{2} \sum_{q=1}^{p} \lambda_{k-j-2,q}^2 \delta_j \right) \delta_j + \sum_{q=1}^{p} \lambda_{k-j-2,q} \epsilon_{j,q} \sqrt{\delta_j} \]

where

\[ \ln F_k(t_1) = \ln F_k(t_0) - \frac{1}{2} \sum_{q=1}^{p} \lambda_{k-1,q}^2 \delta_0 + \sum_{q=1}^{p} \lambda_{k-1,q} \epsilon_{0,q} \sqrt{\delta_0} \]

and \( \epsilon_{j,q} \ (0 \leq j \leq k-1, \ 1 \leq q \leq p) \) are random samples from a standard normal distribution.

Let \( X = \ln F_k(t_k) \), \( Y = \ln F_{k-1}(t_{k-1}) \), \( A = \ln F_k(t_1) \), and \( B = \ln F_{k-1}(t_1) \). Then a two dimensional random variable \((A, B)\) has a bivariate normal distribution with means \( \mu_A \) and \( \mu_B \), variances \( \sigma_A^2 \) and \( \sigma_B^2 \), and correlation coefficient \( \rho \).
and \( \sigma^2_A \), and correlation coefficient \( \rho_{AB} \) where

\[
\mu_A = \ln F_k(t_0) - \frac{1}{2} \sum_{q=1}^p \lambda_{k-1,q}^2 \delta_0
\]

\[
\mu_B = \ln F_{k-1}(t_0) + \left( -\frac{\delta_k F_k(t_0) \sum_{q=1}^p \lambda_{k-1,q} \lambda_{k-2,q}}{1 + \delta_k F_k(t_0)} - \frac{1}{2} \sum_{q=1}^p \lambda_{k-2,q}^2 \right) \delta_0
\]

\[
\sigma^2_A = \sum_{q=1}^p \lambda_{k-1,q}^2 \delta_0
\]

\[
\sigma^2_B = \sum_{q=1}^p \lambda_{k-2,q}^2 \delta_0
\]

\[
\rho_{AB} = \frac{1}{\sigma_A \sigma_B} \sum_{q=1}^p \lambda_{k-1,q} \lambda_{k-2,q} \delta_0
\]

The means \( \mu_A \) and \( \mu_B \) are simplified as

\[
\mu_A = \ln F_k(t_0) - \frac{1}{2} \sigma^2_A
\]

\[
\mu_B = \ln F_{k-1}(t_0) - \frac{\delta_k F_k(t_0) \rho_{AB} \sigma_A \sigma_B}{1 + \delta_k F_k(t_0)} - \frac{1}{2} \sigma^2_B
\]

And a two dimensional random variable \((X, Y)\) given \( A = a \) has a bivariate normal distribution with means \( \mu_X \) and \( \mu_Y \), variances \( \sigma^2_X \) and \( \sigma^2_Y \), and correlation coefficient \( \rho_{XY} \) where

\[
\mu_X = a + \sum_{j=1}^{k-1} \left[ -\frac{1}{2} \sum_{q=1}^p \lambda_{k-j-1,q}^2 \delta_j \right]
\]

\[
\mu_Y = E[B \mid A = a] + \sum_{j=1}^{k-2} \left[ \left( -\frac{\delta_k e^a}{1 + \delta_k e^a} \sum_{q=1}^p \lambda_{k-j-1,q} \lambda_{k-j-2,q} - \frac{1}{2} \sum_{q=1}^p \lambda_{k-j-2,q}^2 \right) \delta_j \right]
\]

\[
\sigma^2_X = \sum_{j=1}^{k-1} \left[ \sum_{q=1}^p \lambda_{k-j-1,q}^2 \delta_j \right]
\]

\[
\sigma^2_Y = \sum_{j=1}^{k-2} \left[ \sum_{q=1}^p \lambda_{k-j-2,q}^2 \delta_j \right] + \text{Var}[B \mid A = a]
\]
\[ \rho_{XY} = \frac{1}{\sigma_X \sigma_Y} \sum_{j=1}^{k-2} \left( \sum_{q=1}^{k} \lambda_{k-j-1,q} \delta_{k-j-2,q} \delta_j \right) \]

\[ E[B \mid A = a] = \mu_b + \rho_{4b} \frac{\sigma_b}{\sigma_A} (a - \mu_A) \]

\[ \text{Var}[B \mid A = a] = \sigma_b^2 (1 - \rho_{4b}^2) \]

The means \( \mu_X \) and \( \mu_Y \) are simplified as

\[ \mu_X = a - \frac{1}{2} \sigma_X^2 \]

\[ \mu_Y = E[B \mid A = a] + \frac{1}{2} \text{Var}[B \mid A = a] - \frac{\delta_k e^a \rho_{XY} \sigma_X \sigma_Y}{1 + \delta_k e^a} - \frac{1}{2} \sigma_Y^2 \]

Note that \( \sigma_X^2 \) and \( \mu_Y \) are independent of the number of factors whereas \( \rho_{XY}, \sigma_Y^2, \) and \( \mu_Y \) depend on the number of factors. The remaining analysis is same as that in the previous section. Therefore, the approximated value of a ratchet caplet with several factors can be calculated using equation (19) with the adjustments only of \( \rho_{XY}, \sigma_Y^2, \) and \( \mu_Y \).
VI. Numerical Results

To validate the accuracy of our approximation methods, a comparison was conducted with the data originally given by Hull [(2002), p.579 – 583]. The principal is $100. The accrual periods are one year in length. The spread is 25 basis points. The term structure is assumed to be flat at 5% per annum with continuous compounding. The caplet volatilities are humped as in Table I. The arithmetic average of the volatilities between one and ten years is 16.71%. Table I also shows volatility components in two- and three-factor models. For the practical usage of our approximation methods, one must decide on the size of $N$ in the Gauss-Hermite integration. The convergences of our two approximation methods are illustrated in Table II. The results are for the tenth ratchet caplet that provides a payoff at time 11 years. Similar results are obtained for other caplets, other term structures, and other volatility structures. Table II shows that the convergences of our two approximation methods are extremely fast. More experiments show that 6-point Gauss-Hermite integration is sufficient to obtain convergence to the sixth decimal place for the most cases. We choose Hull and White’s (2000) Monte Carlo implementation in the rolling forward risk neutral world as our benchmark for the true values. The rolling forward risk neutral world is a world that is always forward risk neutral with respect to a bond maturing at the next reset date. The true values are based on 500,000 Monte Carlo simulations incorporating the antithetic variable technique. To simulate the path followed by the forward rates more precisely, we divide each accrual period into 8 small time intervals. The error measure that we report is root mean squared relative error (RMSE). RMSE is defined by

$$RMSE = \sqrt{\frac{1}{n-1} \sum_{k=2}^{n} e_k^2}$$

where

$$e_k = \frac{\hat{c}_k - c_k}{c_k}$$

is the relative error, $c_k$ is the “true” value of the ratchet caplet that provides a payoff at time $t_{k+1}$ calculated from Monte Carlo simulation, and $\hat{c}_k$ is the approximated ratchet caplet value.

Table III reports results of Monte Carlo simulation and our two approximation methods for one-, two-, and three-factor models. Two approximated values are computed using 6-point Gauss-Hermite quadrature formula with equations (11) and (19), respectively. In Table III, we first notice that the ratchet caplet prices of Monte Carlo and our approximation methods are very close, suggesting the usefulness of our
approximation methods. Table III also shows that, as we expect, the second approximation method is more accurate than the first approximation method. The most dramatic comparison is that of computing times. In Monte Carlo simulation, total computing times for pricing 9 ratchet caplets on a 1.8 GHz Pentium PC are 282, 427, and 485 seconds for the one-, two-, and three-factor models, respectively. The computing times of our two approximation methods are less than hundredth of one second. If we use 100-point Gauss-Hermite quadrature formula rather than 6-point, then total computing times for pricing 9 ratchet caplets are 0.003 and 0.312 seconds for the first and second approximation methods, respectively. Note that the computing times of our two approximation methods are independent of the number of factors.

Tables IV through VI contain a sensitivity analysis of the ratchet caplet values for a range of parameter values. Table IV shows the valuation when the term structure is flat at 20%. Table V shows the valuation when the average volatility is 30%. Table VI shows the valuation when the term structure is flat at 20% and the average volatility is 30%. The general observations drawn from Table III also hold here. Figure 1 graphs RMS errors of our two approximation methods with different values of the interest rate. Figure 2 graphs RMS errors of our two approximation methods with different values of the average volatility. We can see that pricing errors are insensitive for the interest rates and slightly larger errors occur when the volatilities are high.
VII. Conclusion

In this paper, we have presented two analytic approximation formulas for pricing ratchet caps in the LIBOR market model. The results are surprisingly simple and the approximate values of a ratchet caplet are represented as weighted sums of Black’s (1976) regular caplet prices. The weights are from Gauss-Hermite quadrature formula which can be easily calculated from standard numerical packages. So, these approximation formulas are extremely fast and easily implemented. The formulas can be easily extended to incorporate multiple factors. Comparisons with results from Monte-Carlo simulation show that, for the volatility and interest rate environments that are typically encountered in the market, our approximation methods give very accurate results. Although this paper focuses only on the ratchet caplet but the main idea in this paper will be easily applicable to other interest rate derivatives.

(1) The true values are based on 500,000 Monte Carlo simulations incorporating the antithetic variable technique. Each accrual period is divided into 8 equal subintervals.

(2) First approximated values are computed using 6-point Gauss-Hermite quadrature formula with equation (11).

(3) Second approximated values are computed using 6-point Gauss-Hermite quadrature formula with equation (19).
Table V: Valuation of Ratchet Caplets (Average Rate = 5%, Average Volatility = 30%)

The principal is $100. The accrual periods are one year in length. The spread is 25 basis points. The term structure is flat at 5% per annum with continuous compounding and the average volatility is 30% with a bumped volatility structure similar to that of Table 1. RMSE is the root mean squared relative error.

Table VI: Valuation of Ratchet Caplets (Average Rate = 20%, Average Volatility = 30%)

The principal is $100. The accrual periods are one year in length. The spread is 25 basis points. The term structure is flat at 20% per annum with continuous compounding and the average volatility is 30% with a humped volatility structure similar to that of Table I. RMSE is the root mean squared relative error.
