### Abstract

The purpose of this study is to experimentally investigate, at early ages, the fracture characteristics of concrete such as critical crack tip opening displacement, critical stress intensity factor, fracture energy, and bilinear softening curve based on the concepts of the effective-elastic crack model and the cohesive crack model.

A wedge-splitting test for Mode I was performed on cubical specimens with an initial notch at the edge. By taking various strengths and ages, load–crack mouth opening displacement (CMOD) curves were obtained and these curves were evaluated by linear elastic fracture mechanics and finite element analysis.

The results from the test and analysis indicate that critical crack tip opening displacement decreases and critical stress intensity factor and fracture energy increase with concrete ages from Day 1 to Day 28. By numerical analysis, four parameters of bilinear softening curves from Day 1 to Day 28 were obtained. In addition, it was observed that the parameters  $f_i$  and  $f_1$  increase and the parameters  $w_1$  and  $w_c$  decrease with increasing age. The obtained fracture parameters and bilinear softening curves at early ages may be used as a fracture criterion and an input data for finite element analysis of concrete at early ages.

### 1. Introduction

Most cracks in concrete members occur due to thermal stress, autogenous shrinkage, drying shrinkage, and external causes. In actual construction, structures can collapse by cracks occurring at early ages before complete hardening of the concrete. Specifically, it influences durability and service life of concrete structures. Therefore, the evaluation and control of cracks at early ages are essential.

To evaluate this problem, experimental studies on various crack occurrence factors and a systematic crack analysis are required. Especially, it is important to clarify the fracture characteristics of concrete at early ages.

Presently, representative models suggested for failure of concrete can be categorized into two types. One is effective-elastic crack model, which applies linear elastic fracture mechanics (LEFM) for brittle material, and the other is

cohesive crack model, which simulates fracture progression based on softening phenomena occurring only in quasi-brittle materials such as concrete, rock, ice, ceramic, and composite materials.

The purpose of this study is to investigate the material fracture parameters, based on these two models at early ages, such as critical crack tip opening displacement (CTOD<sub>c</sub>), critical stress intensity factor ( $K_{Ic}$ ), fracture energy ( $G_F$ ), and bilinear softening curve, which are considered as fracture characteristics of concrete. These characteristics are evaluated for concrete from an early age to 28 days.

### 2. Test specimens and test results

#### 2.1. Mixture proportioning

The concrete mixture proportions selected for the wedge-splitting test (WST) and 28-day compressive strength cylinder specimens are listed in Table 1. Type I Portland cement was used. Maximum aggregate size  $d_a$  was 19 mm

and a high-range water-reducing admixture and vibrator were used to improve the workability and consolidation of the concrete.

## 2.2. Details of test specimens

The dimensions and shape of WST specimens used in the experiments are shown in Fig. 1. An initial crack was made by inserting a steel plate (1 mm in this study) inside the specimen during the casting and then removing the plate after 1 day. A groove was made in the upper part of specimen to place two load devices with roller bearing and to attach the displacement gages (i.e., CMOD clip gage).

All WST specimens and test cylinders were removed from the mold after 24 h and were wet-cured in a curing room with 100% relative humidity (RH) at  $23 \pm 2$  °C until the testing date.

In this study, a single specimen size was adopted due to the limitation of the testing machine. However, many experimental and theoretical investigations show the fracture toughness dependency to specimen size variation. Bazant and Li [1] suggested a procedure to evaluate the effect of size differences for one type of concrete and single-size fracture specimens. Currently, however, there is no definite method and further studies are necessary. In a follow-up study, size effect on fracture characteristics of concrete at early ages will be reported.

## 2.3. Test procedure

In this study, the wedge-splitting specimen, initially proposed by Linsbauer and Tschegg [2] and later modified by Brühwiler and Wittmann [3] was used. The principle of the WST is schematically represented in Fig. 2. The specimen is placed on a line support fixed to the lower plate of the testing machine (Fig. 2a). Two massive steel loading devices equipped with roller bearings on each side are placed on the top of the specimen (Fig. 2b). A steel profile with two identical wedges is fixed at the upper plate of the testing machine. The actuator of the testing machine is moved so that the wedge enters between the bearings, which results in a horizontal splitting force component (Fig. 2c). Laboratory test setup and test specimen is shown in Fig. 3. From a testing standpoint, the cracking process can be controlled and monitored using the crack mouth opening

displacement (CMOD) shown in Fig. 4 [4]. Some notations are also illustrated in this figure.

The fracture section of the specimen is essentially subjected to a bending moment. The vertical load does not affect the crack propagation. The load in the vertical direction and the crack opening displacement (COD) at two points along the crack surface and the location of roller axis are monitored during testing. The rate of loading was controlled by a constant rate (0.002 mm/s) of increment of COD at the location of roller axis. The specimen was monotonically loaded up to the peak load.

## 2.4. Test results

The specimens for low-, normal-, and high-strength concrete are assigned with LS, NS, and HS as the specimen names, respectively. Concrete compressive strength  $f'_c$ , splitting tensile strength  $f_{ct}$ , and compressive elastic modulus  $E_c$  were determined based on an averaged result of three identical  $\phi 100 \times 200$  mm cylinders. Table 2 tabulates the experimental data of  $f'_c$ ,  $f_{ct}$ , and  $E_c$  of the concrete cylinders where concrete from the same batch was used to cast the WST specimens.

Fig. 5 contains the plots of the averaged value of horizontal load components versus CMOD for the two WST results for LS, NS, and HS, respectively. Fig. 6 shows the average value of CODs, which were obtained at three points located on the constant distance from the initial crack tip, at the peak load. The test results in Fig. 5 show that the load increases as the CMOD increases; however, the value rapidly decreases after a certain point. Point corresponding to the maximum load in Fig. 5 was considered as the critical point, which can be the beginning point of unstable crack progression.

The stages of opening (Mode I) crack growth for a notched specimen shown in Fig. 4 are related to the load–displacement curve shown. In this curve, stable crack growth begins to propagate as the applied load or displacement increases up to the point. Even though the applied load remains constant or decreases, if the load control

Fig. 1. Geometry and size of specimen.

Fig. 2. Principle of WST.

Fig. 3. Laboratory test setup and test specimen.

method is used, the crack propagation can be unstable beyond this point [5]. In this study, however, the displacement control method was used. Accordingly, the testing machine had a way to control it and unstable crack progression did not occur.

Fig. 6 shows that the values measured at three points have a linear relationship. This is related to crack opening profile (shape) (COP), which is discussed in detail in the next section. In this figure, the range of COD values with age is reduced as the strength increases. Fig. 5, load–CMOD curves, is used to obtain the value  $G_F$  and the bilinear softening curves. In addition, COD at the peak load (Fig. 6) is used to obtain the values  $CTOD_c$  and  $K_{Ic}$ .

### 3. Analysis and evaluation

#### 3.1. Analysis method

To obtain the values  $CTOD_c$  and  $K_{Ic}$ , which are fracture characteristics based on the effective-elastic crack model, the effective-elastic critical crack length  $a_{ec}$  should be determined first. The values  $CTOD_c$  and  $K_{Ic}$  are fracture parameters used to describe fracture response at the peak load. According to the two-parameter fracture model by Jenq and Shah [6], to obtain the value  $a_{ec}$ , which causes elastic fracture response of structures, the test is performed

Fig. 4. Stages of Mode I crack growth: (a) initiation of stable crack growth, (b) process zone partially developed, and (c) start of unstable crack growth at peak load [4].

by loading the specimen under CMOD control up to the point beyond the maximum load and then it is unloaded and reloaded.

In Jenq and Shah’s model, the value  $a_{ec}$  may be defined in such a way that it results in an unloading compliance  $C_u$  within 95% of the peak load based on LEFM. However, it is difficult to select the beginning point of unloading and to

calculate the value  $C_u$  from the load–CMOD curve. Accordingly, in this study, the COP based on LEFM, rather than the unloading compliance, is used to determine the value  $a_{ec}$ . This may be expressed as

$$COD(a, x) = CMOD \times g\left(\frac{a}{d}, \frac{x}{a}\right) \tag{1}$$

$$g\left(\frac{a}{d}, \frac{x}{a}\right) = \left\{ \left(1 - \frac{x}{a}\right)^2 + \left(0.94 - 1.11 \frac{a}{d}\right) \left[\frac{x}{a} - \left(\frac{x}{a}\right)^2\right] \right\}^{1/2}$$

where  $g$  is the COP function obtained from the finite element (FE) analysis for the WST specimens;  $a$  is the crack length;  $d$  is the characteristic dimension of a member (in this study,  $d$  is regarded as the length from bottom face of a specimen to roller axis); and  $x$  is the distance from the roller axis. Namely, Eq. (1) represents the value COD with  $x$  as the function of CMOD. The  $g$  function curves for different crack lengths are shown in Fig. 7. Fig. 7 shows that the shape of curves around the crack tip is nonlinear, and as it becomes more distant from the crack tip it shows a linear relationship. This is consistent with experimental results. Namely, the values of COD, which was measured at three points (i.e. roller axis,  $x_1$ , and  $x_2$  spaced from the crack tip), show nearly a linear relationship.

Fig. 5. Horizontal load–CMOD curves.

Two equations for the value  $a_{ec}$  can be obtained by substituting two COD( $x$ ) values measured at  $x_1$  and  $x_2$  into Eq. (1). Then, by solving Eq. (1), two values for  $a_{ec}$  can be determined and, finally, we can obtain the value  $a_{ec}$  by averaging these values. After the value  $a_{ec}$  is determined, the value CTOD<sub>c</sub> can be obtained. The value CTOD<sub>c</sub> is determined by substituting the values of  $a_{ec}$ , CMOD, and  $a_o$  into Eq. (1), where the values  $a_o$  and  $a_{ec}$ , respectively,

instead of  $x$  and  $a$ , should be used. Finally, the value  $a_{ec}$  as well as the critical (peak) load  $P_c$  is further substituted into Eq. (2), which is suggested by Murakami [7] to calculate the value  $K_{Ic}$ .

$$K_{Ic} = \frac{P_c}{b\sqrt{d}} F(\alpha) \tag{2}$$

$$F(\alpha) = 29.6\alpha^{0.5} - 185.5\alpha^{1.5} + 665.7\alpha^{2.5} - 1017.0\alpha^{3.5} + 638.9\alpha^{4.5}$$

where  $F(\alpha)$  is derived by Zhao et al. [8] for conventional WST specimens (i.e.  $l/d = 1.2$ ) like those of this study;  $b$  is

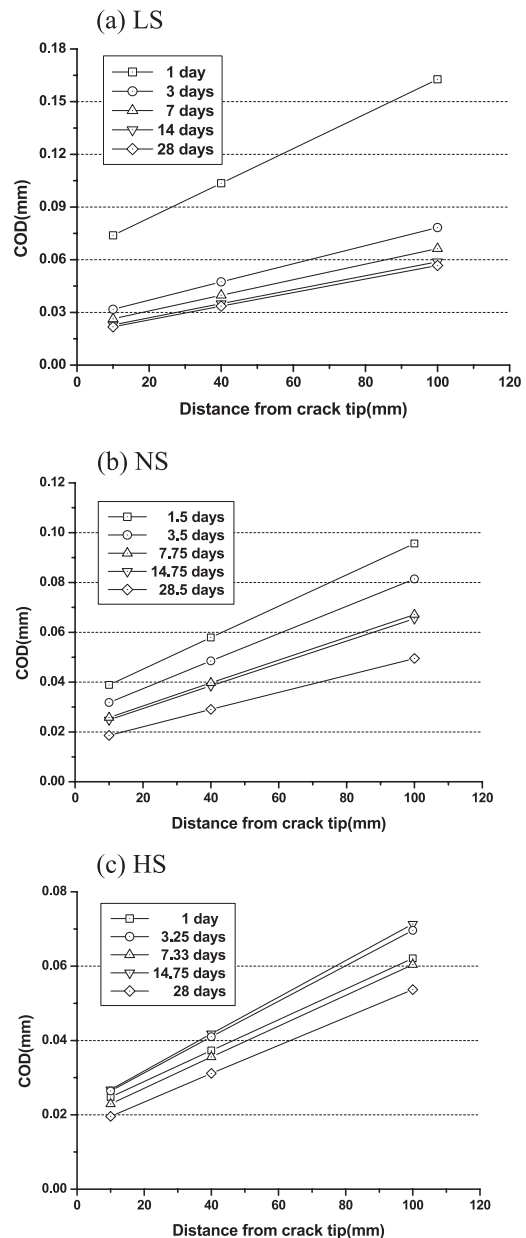

Fig. 6. COD at peak load.

Fig. 7. COP function for WST specimen.

the thickness of a specimen;  $l$  is the length of a specimen;  $d$  is the length from bottom face of a specimen to roller axis;  $F(\alpha)$  is the constant given by the initial crack length  $a_0$ ; and  $\alpha$  is  $a/d$ . Based on the obtained load–CMOD curve of Fig. 5, the fracture energy  $G_F$  can be calculated.

3.2. Analysis results

Fracture characteristics obtained from the analyses are graphed and shown in Figs. 8–11 and Table 3. Based on critical effective crack extension  $\Delta a_{ec}$  (where the value  $\Delta a_{ec}$  is given by  $a_{ec} - a_0$ ) indicated in Fig. 8, it is noted that crack propagates more up to the peak load as strength is lower and age is younger. In addition, as predicted in the COD shape of Fig. 7, the value  $CTOD_c$  in Fig. 9 also increases with lower strength and younger age. There is a similar pattern with  $\Delta a_{ec}$ . According to Figs. 10 and 11, the values  $K_{Ic}$  and  $G_F$  increase with increasing age, especially increasing rap-

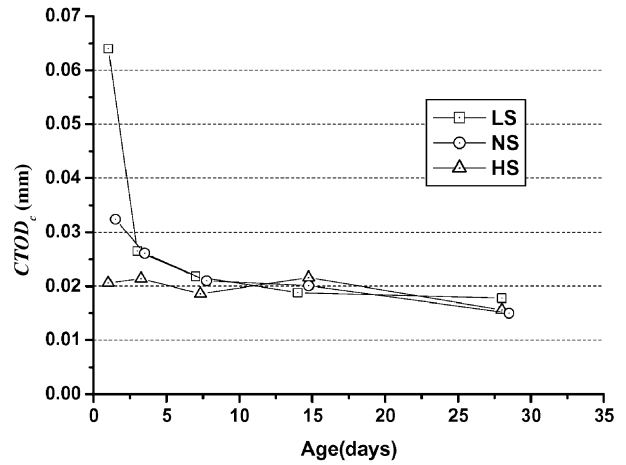

Fig. 9.  $CTOD_c$  at various ages.

idly at early ages, and converging to a limit at 28 days. This means that the fracture toughness increases rapidly with increasing early age after the casting. The values  $K_{Ic}$  are compared with the results obtained from three-point bend beam tests at 0.5, 1, 7, 21, and 28 days by Zollinger et al. [9]. Although there is a difference in the results due to the difference of materials and experimental methods used, it seems the trend is similar.

3.3. Bilinear softening curve by numerical analysis

A typical softening curve of concrete is shown in Fig. 12. Petersson [10] proposed a method for equating the softening curve with the bilinear softening curve as shown in Fig. 13. This indicates that the softening curve (i.e., the curve is the one of fracture characteristics of concrete) can be simplified by determining  $f_t$ ,  $f_1$ ,  $w_1$ , and  $w_c$  values. It is noted that the bilinear curve can be completely determined

Fig. 8. Critical effective crack extension  $\Delta a_{ec}$  at various ages.

Fig. 10.  $K_{Ic}$  at various ages.

Fig. 11.  $G_F$  at various ages.

if the  $f_t$ ,  $f_1$ ,  $w_1$  and  $w_c$  values are known. In this study, FE analysis was carried out based on the cohesive crack model and the principle of superposition suggested by Gopalaratnam and Ye [11] in 1991. First, from crack analysis using superposition we can obtain the independent elastic solution for the external load and a unit load applied at point  $x$  along the crack surfaces of fracture process zone (FPZ). Second, to satisfy equilibrium equation, compatibility condition, and cohesive stress–COD relationship in the FPZ for overall structures, a series of equation systems is composed.

In this study, the stress condition was assumed as plane-stress and the specimen configuration and the finite element mesh used for numerical investigation are shown in Fig. 14. As an input data for FE analysis, initial tangent modulus in tension  $E_0 \approx 1.5E_c$  was used. This modulus was selected from trial and error method by FE analysis to

Fig. 12. Softening curve of concrete.

obtain the closest approximation to load–CMOD curves shown in Fig. 5. Where  $E_c$  is the compressive elastic modulus.

Only half of the specimen needs to be considered due to symmetry. There were a total of 390 elements (two-dimensional parabolic isoparametric element) and 23 nodes on the ligament length  $d - a_0$  where the crack propagates. At these nodes, the load–COD relationship for FE analysis was obtained using the nonlinear spring element, which shows the bilinear softening phenomena. From the load–CMOD curve, four parameters for bilinear softening curve,  $f_t$ ,  $f_1$ ,  $w_1$  and  $w_c$ , can be obtained. To obtain the optimum solution for the load–CMOD curve, the following function is used.

$$F(f_t, f_1, w_1, w_c) = \int_0^{CMOD_0} (P_e - P_m)^2 d\delta \quad (3)$$

where  $P_e$  is the load obtained from the tests,  $CMOD_0$  is equal to an ideal value CMOD when the load is 0.0, and  $P_m = P_m(f_t, f_1, w_1, w_c)$  is the load obtained from FE

analysis. The function  $F(f_t, f_1, w_1, w_c)$  represents the difference between the load–CMOD curve obtained from the tests and the load–CMOD curve obtained from the analysis. Therefore, the softening curve can be said to be

	28.5	2.8304	0.6275	0.0133	0.2101	0.1067
HS	1	1.7758	0.4023	0.0181	0.2749	0.0287
	3.25	2.6245	0.5677	0.0156	0.1722	0.1180
	7.33	2.6315	0.6743	0.0166	0.1822	0.1444
	14.75	3.0572	0.6865	0.0159	0.1746	0.1877
	28	3.3044	0.6638	0.0149	0.1646	0.1443

more accurate when  $F(f_t, f_1, w_1, w_c)$  has a minimal value. The condition is shown in Eq. (4).

$$\frac{\partial F}{\partial f_t} = \frac{\partial F}{\partial f_1} = \frac{\partial F}{\partial w_1} = \frac{\partial F}{\partial w_c} = 0 \quad (4)$$

Eq. (4) shows four nonlinear equations. To solve these equations, the Newton–Raphson iteration method was

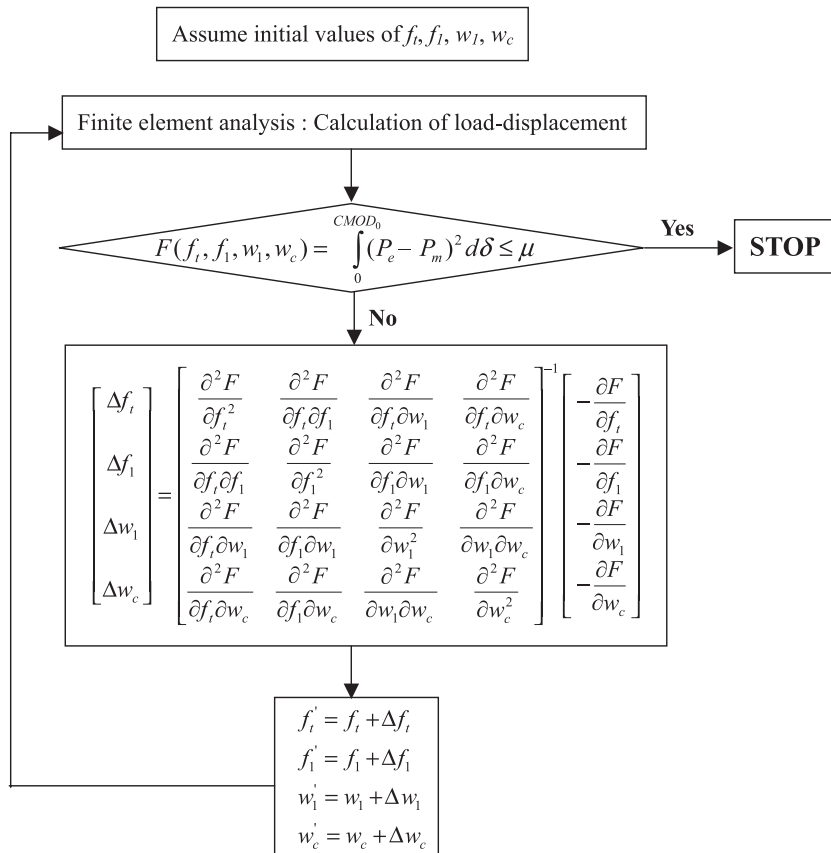

Fig. 15. Flow chart of the numerical procedure.

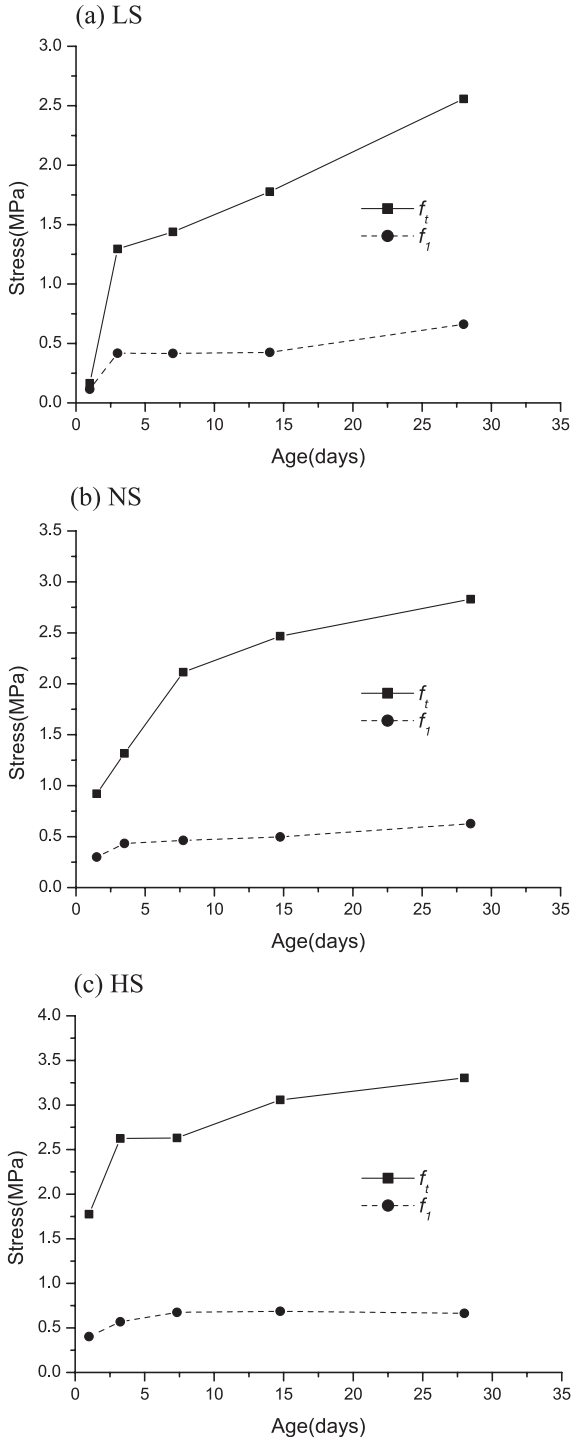

Fig. 16. Variation of parameters  $f_t$  and  $f_1$  with age.

used. The procedure is shown in Fig. 15 [12–14]. The differential terms of  $F(f_t, f_1, w_c, w_1)$  shown in Fig. 15 can be calculated by numerical method as shown in Eq. (5) [14].

$$\frac{\partial f}{\partial x} \approx \frac{f(x+h) - f(x-h)}{2h} \quad (5)$$

$$\frac{\partial^2 f}{\partial x^2} \approx \frac{f(x+h) + f(x-h) - 2f(x)}{h^2}$$

$$\frac{\partial^2 f}{\partial x \partial y} \approx \frac{f(x+h, y+g) + f(x-h, y-g) - f(x+h, y-g) - f(x-h, y+g)}{4hg}$$

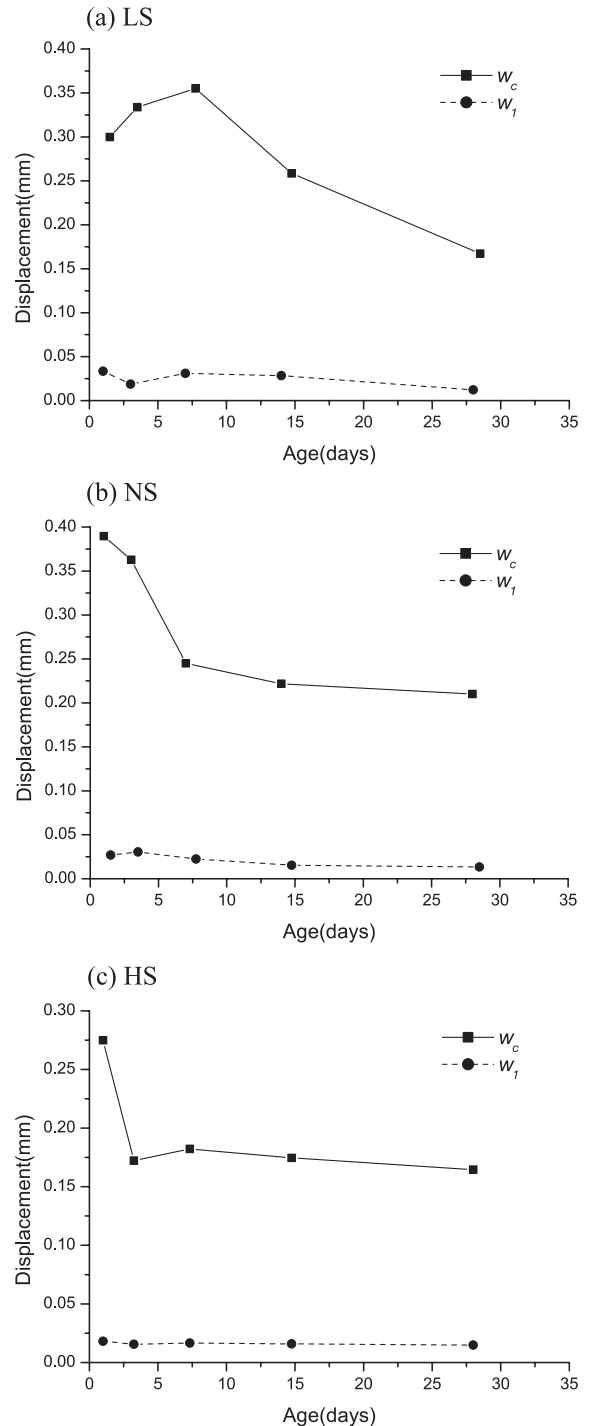

Fig. 17. Variation of parameters  $w_c$  and  $w_1$  with age.

where the values  $g$  and  $h$  are sufficiently small positive constants.

The parameters  $f_t$ ,  $f_1$ ,  $w_1$ , and  $w_c$  for bilinear softening curves obtained from numerical analysis are summarized in Table 4, Fig. 16, and Fig. 17. According to Figs. 16 and 17, the parameters  $f_t$  and  $f_1$  increase and the parameters  $w_1$  and  $w_c$  decrease as age increases. This is because the peak load and the brittleness of load–CMOD curve with age increases up to the peak load. However, the curve shows more rapid softening phenomena after the peak load with increasing age.

In the ideal case, the minimum value of  $F(f_t, f_1, w_1, w_c)$  shall be 0.0. In this study, however, due to experimental and analytical reasons, this value is not 0.0 but is a positive constant. According to Table 4, the averaged values of  $F(f_t, f_1, w_1, w_c)$  are 0.0370, 0.0459, and 0.1246  $\text{kN}^2 \text{mm}$ , respectively, in cases of LS, NS, and HS. However, if we consider that the integral limit ( $\text{CMOD}_0$ ) is 2.0 mm, the errors are 0.136, 0.151, and 0.250 kN on each CMOD value of load–CMOD curves, respectively, for LS, NS, and HS cases. The reasons for the increase of these errors as the strength increases are that the peak load increases on the

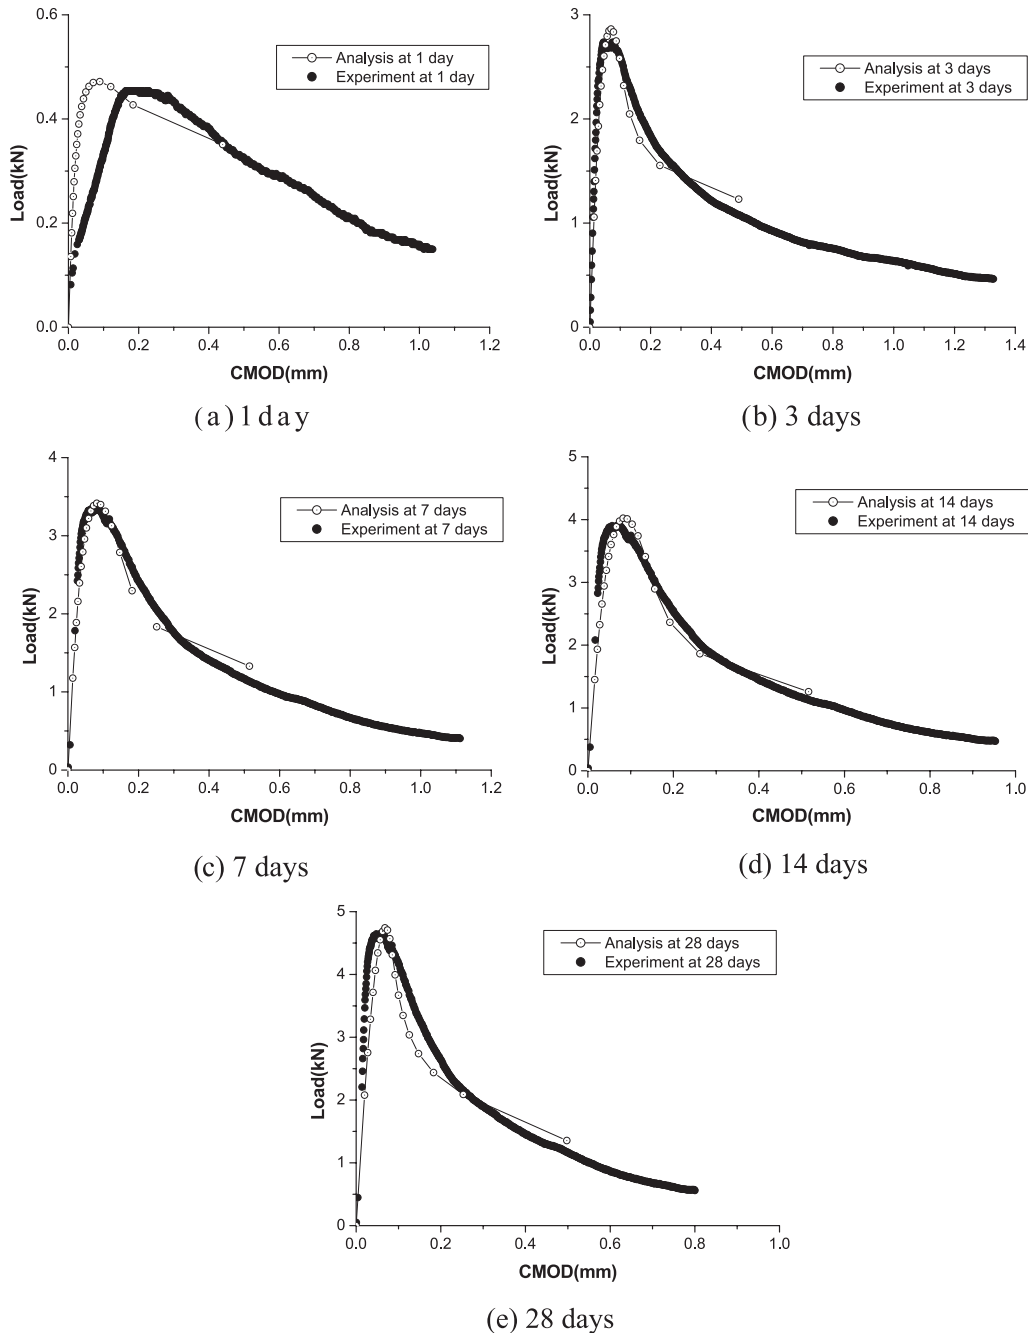

Fig. 18. Load–CMOD curves with age for LS (numerical analysis).

load–CMOD curve and the load reduction happens more rapidly after the peak load as the strength increases. In this study, for three levels of strength, the same number of nodes on the ligament in which the crack propagates is used. Accordingly, the error increases around the load transition point as the strength increases. For HS, to reduce the error, the number of nodes on the ligament should increase.

It is seen in Figs. 18–20 that load–CMOD curves from the analyses using four parameters obtained are comparable with ones from the tests. In Fig. 18(a), however, a considerable difference is evident because the load–

CMOD curve at 1 day for LS is severely nonlinear up to the peak load.

#### 4. Conclusions

In this study, fracture characteristics of concrete with age, specifically at early ages, were investigated and the results can be summarized as follow:

1. Instead of performing an unloading cycle on the route of experiments, the value  $a_{ec}$ , which the effective-elastic

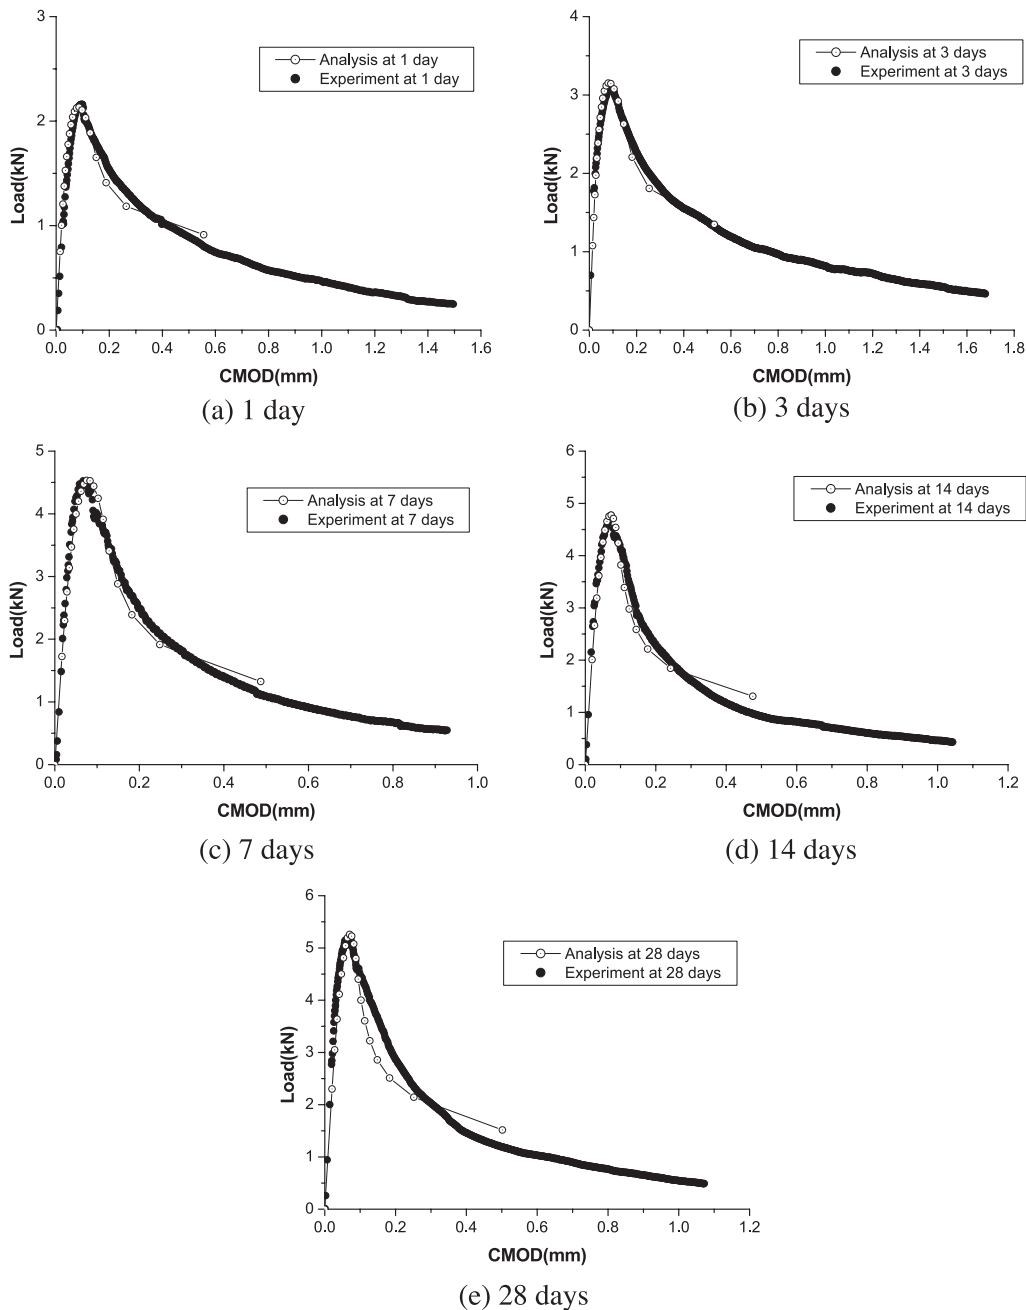

Fig. 19. Load–CMOD curves with age for NS (numerical analysis).

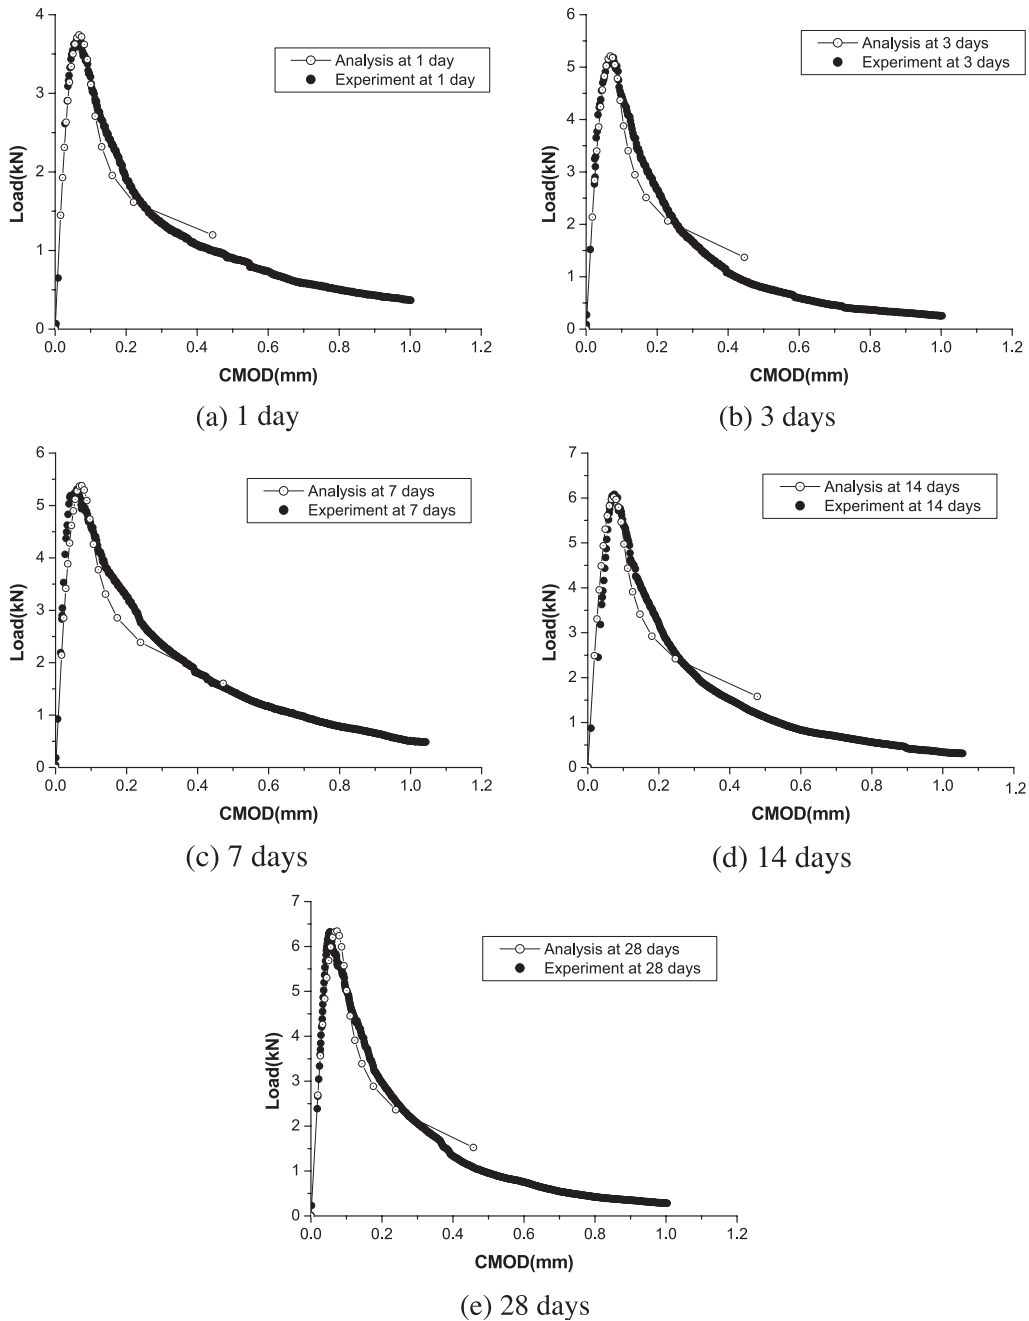

Fig. 20. Load–CMOD curves with age for HS (numerical analysis).

crack model defines, was derived using the results obtained from the stable WST and the COP for WST specimens.

2. Using the value  $a_{ec}$ , the values  $CTOD_c$  and  $K_{Ic}$ , which are fracture characteristics, for concrete at early ages were obtained. The value  $G_F$  for concrete at early ages was determined based on the load–CMOD curve obtained from the WST.
3. Based on the cohesive crack model, the bilinear softening curves of concrete at early ages were determined by comparing the load–CMOD curve obtained from FE analysis of specimens used in this study with the load–CMOD curve obtained from the tests.

4. The derived fracture parameters and bilinear softening curves at early ages may be used as a fracture criterion and input data for FE analysis of concrete at early ages.

## 5. Further experiment

Because this experimental study was conducted for a single specimen size and measurements were performed when the FPZ has not yet attained a steady-state size, further experimental work involving the specimen sizes decreasing and increasing at early ages would be required.

### Notation

$a$	crack length
$a_c$	critical crack length
$a_o$	initial crack length
$a_{ec}$	effective-elastic critical crack length
$b$	thickness of a specimen
$C_u$	unloading compliance within 95% of the peak load for load–CMOD curve
COD	crack opening displacement
COP	crack opening profile
CMOD	crack mouth opening displacement
CMOD <sub>c</sub>	critical crack mouth opening displacement
CTOD	crack tip opening displacement
CTOD <sub>c</sub>	critical crack tip opening displacement
CMOD <sub>0</sub>	CMOD value when the load is 0.0
$d$	length from bottom face of a specimen to roller axis
$d - a_o$	ligament length
$d_a$	maximum aggregate size
$E_c$	compressive elastic modulus of concrete
$E_o$	initial tangent modulus in tension
$f'_c$	compressive strength of concrete
$f_{ct}$	splitting tensile strength of concrete cylinder
$f_b, f_1, w_1, w_c$	four parameters for bilinear softening curve
$g$	crack opening profile function
$G_F$	fracture energy
$K_{Ic}$	critical stress intensity factor
$l$	length of a specimen
$P$	applied force
$P_c$	critical (peak) load
$P_e$	load obtained from the tests
$P_m$	load obtained from FE analysis
$x, x_1, x_2$	distance from the roller axis along the crack surface
$\Delta a_{ec}$	critical effective crack extension length

### Acknowledgements

The authors would like to thank the Korea Institute of Science and Technology Evaluation and Planning (KISTEP)

for the financial support of the National Research Laboratory (NRL).
